14. ABSTRACT This report documents the initial phases (model development) of a DoD Challenge project investigating the interactions of organophosphorus compounds with acetylcholinesterase. This project entails characterization of the structural features, which lie at the heart of the interaction between novel organophosphorus compounds (or other more reversible inhibitors) and the enzyme acetylcholinesterase. Large biological systems present inherent difficulties to the modeling community. We are using quantum chemical and mixed quantum/classical techniques, QM/MM, to examine structural effects of reactions involving novel organophosphorus compound in the active site of the enzyme, as well as the role of surrounding residues. This investigation will provide highly accurate and reliable characterizations of the biochemical processes responsible for both activity and inhibition of novel organophosphorus compounds. It is expected that the results should prove relevant to toxicological endeavors within the medical and non-medical community alike.

## **PREFACE**

This report documents the research efforts of the FY 2002 DoD Challenge Project, SSSCON00623C71, entitled "Interactions of Chemical Warfare Agents with Acetylcholinesterase." The work was carried out between October 2001 and November 2002, under the program element number 622786.

Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the U.S. Army Soldier and Biological Chemical Command, Soldier Systems Center, Natick, MA.

## **ACKNOWLEDGEMENTS**

This work was supported in part by a grant of computer time from the DoD High Performance Computing Modernization Program at the Army Research Laboratory (ARL), the Aeronautical Systems Center (ASC), and the US Army Engineer Research and Development Center (ERDC) Major Shared Resource Centers (MSRCs). Partial funding has been provided through a DoD Joint Science and Technology Panel for Chemical Biological Defense (JSTPCBD) proposal.

## COMPUTATIONAL STUDIES ON ACETYLCHOLINESTERASE: RESULTS FROM A FY 2002 DOD CHALLENGE PROJECT

### SUMMARY

The nerve agent class of chemical warfare agents function by irreversibly inhibiting acetylcholinesterase (AChE), thereby leading to the uncontrolled accumulation of acetylcholine in the neuro-neuro and neuro-muscular junctions causing a variety of life-threatening symptoms. The molecular interactions that hold the enzyme in its optimal conformation and promote catalysis have never been elucidated. As a result, toxicity predictions of novel agents and antidote effectiveness can only be made by extrapolations from closely related analogs. A sound theoretical basis would allow reasonable predictions on compounds unrelated to those already studied. The methodology described herein, derived from the expertise and successful collaboration between the U.S. Army Soldier and Biological Chemical Command (SBCCOM), the Army Research Laboratory (ARL), and the University of Kansas, provides an effective means for achieving this mission-mandated requirement.

The goals of this project using QM (quantum mechanical calculations), QM/QM and QM/MM (quantum mechanics embedded in molecular mechanic calculations) entail (1) determination of the molecular basis for enzymatic hydrolysis of acetylcholine and inhibition of AChE by organophosphorus (OP) compounds, including investigation of stereochemical effects and explicit solvation, (2) comparison of the transition state structures of the enzyme catalyzed path from the reaction in aqueous solution, (3) examination of the regeneration of inhibited enzymes by oximes and other nucleophiles, including examination of competing pathways such as the aging process, and (4) examination of current and potential pretreatment compounds. This project will impact the design of therapeutic and prophylactic

treatments for OP compound exposure through increased understanding of interactions in the active site of AChE and the enzyme as a whole.

Theoretical calculations have been performed on this enzyme for several years; however, until our recent award of two DoD High Performance Computing (HPC) Challenge grants and partial funding from a DoD Joint Science and Technology Panel for Chemical Biological Defense (JSTPCBD) proposal, the lack of sufficient computing power placed severe limitations on the rigor of the method and the extent of the active site model. Utilization of HPC resources provides a useful complement to experimental studies, helping to focus costly experiments while providing understanding of reactions at the atomistic level to gain much-needed insight. While prior calculations were restricted either to low levels of theory, or to truncated analogs containing only the amino acids in the active site, we have recently acquired the capacity for highly sophisticated simulations in which all relevant reactivity is treated with correlated electronic structure methods, and is effectively embedded in a lower level model capable of accounting for many important environment effects.

## 1. INTRODUCTION

The enzyme acetylcholinesterase (AChE) has been a topic of interest to theoreticians and experimentalists alike for a number of years. A large amount of this effort in the medical and academic communities has been in the course of investigating diseases such as Alzheimer's and myasthenia gravis. However, the enzyme has remained of key interest for military and civilian security personnel for the role it plays in nerve agent activity and inhibition. Organophosphorus (OP) compounds such as nerve agents and insecticides are toxic chemicals that inhibit the function of AChE (Eto, 1974). Acetylcholine, a neurotransmitter, has an important role of transmitting electrical impulses across neuro-neuro

or neuro-muscular junctions (synapses). Acetylcholine is released at a nerve end (axon end), travels across the synapse to the receptor site on the post-synaptic membrane and stimulates another neuron or muscle fiber. The active acetylcholine in the synaptic cleft is immediately hydrolyzed to inactive choline and acetate via the serine residue of AChE in a two-step process. In the transesterification step, the acetate moiety is transferred from the choline to a serine residue on the active site of the enzyme. In the second step, water hydrolyzes the acetylated serine to form acetic acid and regenerate the enzyme for subsequent acetylcholine catalysis (Figure 1) (Taylor and Brown, 1994).

**Figure 1.** Schematic of the transesterification of acetylcholine and the regeneration of AChE via hydrolysis.

As is the case for carbonyl esters, the serine anion is capable of attacking phosphorus esters and carbamates. Unfortunately, water does not have sufficient nucleophilic strength to hydrolyze the phosphorylated or carbamylated serine. Thus, with these substrates, the enzyme active site becomes blocked leading to the uncontrolled accumulation of acetylcholine at the neuro-neuro and neuro-muscular junctions, causing a wide variety of life-threatening toxic effects (Figure 2) (Heilbronn, 1993; (Schwartz, 1985).

A key feature of the enzyme active center is the catalytic triad, which consists of serine-200, histidine-440, and glutamate-327 (residue numbering according to *Torpedo Californica* AChE structure (Harel et al., 1996)). An important aspect of the catalysis is the facile formation of the nucleophilic serine anion. To form this anion, a proton is transferred from the hydroxyl group on Ser-200 to a nitrogen atom in the imidazole ring of His-440.

**Figure 2.** Schematic of the phosphorylation of AChE and the subsequent accumulation of acetylcholine.

Simultaneously, a proton is transferred from the other nitrogen in the ring to the carboxyl group on Glu-327. This proton transfer is expected to proceed concurrently with the nucleophilic attack on the carbonyl group of acetylcholine (or the phosphonyl group on Methyl Methylphosphonofluoridate as depicted in Figure 3). An important additional structural feature is the nearby oxyanion hole (Gly-118, Gly-119, and Ala-201 in the *Torpedo* numbering), which performs the function of stabilizing the negative charge developing on the anionic moiety of the ligand (Figure 3).

**Figure 3.** Significant residues of the active site of AChE (*Torpedo Californica*) with a generic OP compound, Methyl Methylphosphonofluoridate. For simplicity, only the significant protons are depicted. The catalytic triad consists of Ser-200, His-440, and Glu-327. The oxyanion hole consists of Gly-118, Gly-119, and Ala-201. The Ser-200 hydroxyl group is lined up opposite to the phosphinate fluoride. The phosphinyl group is coordinated in the oxyanion hole.

During the last half century, considerable empirical data has emerged regarding the substrate/activity relationships of AChE, rates of inhibition, and nucleophiles for removing the adducts, and a considerable body of literature pertaining to agent toxicity and prophylaxis

has evolved (Broomfield et al., 1999; (Doctor et al., 1999; (Millard et al., 1999; 2001). However, a detailed understanding of the mechanistic underpinnings and systematic anatomization of AChE inhibition, regeneration, and aging has remained elusive, in part due to the system size and complexity. Many early approaches entailed semi-empirical calculations on a truncated trypsin enzyme containing the active center and a few additional amino acids (Daggett et al., 1991). The main alternatives to semi-empirical methods have been the fully empirical techniques such as classical molecular dynamics (MD) and molecular mechanics (MM) wherein the entire protein may be studied, but at the expense of omitting explicit electronic structural effects that are fundamental to reliable prediction of chemical reactivity (Albaret et al., 1997; (Fuxreiter and Warshel, 1998).

Among the most important prior efforts in AChE activity modeling is that of Kovach et al., who employed a variety of techniques (including MM, MD and *ab initio* quantum chemical formalisms) to study AChE substrate binding and transition state structure (Bencsura et al., 1996). Via quantum chemical means, it was possible to determine a candidate structure for a prospective pentavalent transition state and develop a classical force field from those calculations. The pentavalent phosphonate was then placed inside the enzyme active site, and binding to the neighboring amino acid residues was studied. These latter studies were fundamentally limited, however, in that the absence of explicit electronic structural information in the classical model precluded a reliable simulation of bond breakage and activation energy prediction for the reaction. Additional formidable MD work on AChE has been performed by McCammon and coworkers to address complex structural issues involving solvation, the hypothetical “back door” to the active site, and gating of the gorge (Shen et al., 2001; (Tai et al., 2001).

While classical MD work and truncated QM models of AChE have been the rule, a notable exception is the QM/MM work of Vasilyev (Vasilyev, 1994), who used a combination of PM3 and the OPLS force field to study protonation within the catalytic triad, as well as inhibition by a simple organophosphate  $P(F)(O)(NH_2)(CH_3)$ . It is important to note that in this model only the catalytic triad side chains and the substrate were studied at the quantum level, and the surrounding enzyme environment was held fixed.

Similar enzyme processes have been the focus of theoretical studies performed with a variety of clever techniques to obviate the problems associated with inadequate computer power. Of particular interest is a recent QM/MM study of the catalytic mechanism for citrate synthase (Mulholland et al., 2000), which is relevant to the current effort as it involves the transfer of a methyl proton on acetyl CoA to aspartate-375 and the possible protonation of the carbonyl oxygen by histidine-274. Also extremely relevant are the QM/MM studies of Topf et al. on the deacylation step of the serine protease elastase (Topf et al., 2001).

This paper represents initial results in an attempt to use QM, QM/QM and QM/MM methodologies to provide accurate and reliable characterization of model OP compound activity and inhibition of the AChE active site. Two methodologies, the ONIOM method (Dapprich et al., 1999) and the related SIMOMM method (Shoemaker et al., 1999), are used to study both bare AChE, and a series of systems involving model OP compounds. The roles of model size, force field, and methodology are examined, as well as the chemical structure of the catalytic triad (including the existence of the Short Strong Hydrogen Bond or SSHB), which are a vital aspect of the efficacy of the enzyme. The energetics, transition state formation, and the role of the oxyanion hole are being investigated.

## 2. METHODS

### 2.1 Codes

The Integrated Molecular Orbital Molecular Mechanics (IMOMM) methodology of Morokuma was one of the early QM/MM implementations available to the non-specialist user (Maseras and Morokuma, 1995). A number of academic and commercial codes still rely on permutations of this algorithm. ONIOM calculations in this work have been performed using the Gaussian codes (Frisch et al., 1998). This work has been performed on several size models of the AChE active site, both with and without a model OP compound. In addition, these results have been augmented by calculations performed using the IMOMM-based SIMOMM, Surface-IMOMM, method of Burggraf et al. as implemented in the General Atomic and Molecular Electronic Structure System code (GAMESS-US) (Schmidt et al., 1993). This implementation uses the Tinker package of Ponder et al. (Pappu et al., 1998) for the MM component. One of the major conceptual differences between ONIOM and SIMOMM lies in the treatment of atoms in the MM region that are directly bound to the QM region (which will be referred to here as “boundary atoms”), and in treatment of the atoms (typically hydrogens) added to the QM region to terminate dangling bonds. Boundary atoms in ONIOM represent a specific subset of the bulk region and are fixed during the optimization. In the SIMOMM method, boundary atoms are treated no differently than the rest of the MM region and are allowed to optimize in response to the MM gradient. Similarly, termination atoms in the QM region are fixed in the ONIOM method, yet optimized in SIMOMM in response to the QM gradient. It is the contention of the SIMOMM developers that this improves the calculation by removing user-defined constraints. Additional trivial differences arise in terms of available force fields, etc.

## 2.2 Enzymes/ Methodology

A number of reliable experimentally derived crystal structures for various forms of AChE are available. Crystal structures for both *Torpedo Californica* and *Mus Musculus* (1AMN and 1MAA) have been obtained from the RCSB databank and have been used to obtain starting structures. Due to the sheer size of the enzyme (over 5000 heavy atoms), calculations have been performed using the “Ribbon Methodology.” This methodology consists of collecting all the enzyme atoms surrounding the active site serine hydroxyl group out to a predefined distance (Figure 4A) thus eliminating the need to truncate the active site residues. All atoms outside of the sphere are eliminated. This will leave segments of the overall enzyme ribbon inside the sphere (Figure 4B). The ends of each ribbon segment are locked in space. This “Ribbon Methodology” will permit structural relaxation of the active site atoms and flexible response to the insertion of model OP compounds. In other words, this methodology will allow enough flexibility in the active site to investigate the chemistry but retains sufficient rigidity such that the active site does not fall apart. The main consequence of this flexible methodology is the elimination of the use of expensive solvation methods since a predefined layer of enzyme atoms surrounds the active site chemistry being investigated.

**Figure 4.** A) CPK model of a sphere of atoms with a radius of 10 angstroms from the Ser-200 hydroxyl group in the active site. B) The corresponding ribbon structure showing the five ribbon segments whose ends terminate on the sphere surface.

Various model sizes have been investigated, ranging from a small model (containing only the active site residues plus a model OP compound), to an intermediate model (containing the active site residues, the oxyanion hole residues and the model OP compound), to two larger models (comprised of all residues which at least partially reside within a 7- or 10-angstrom radius of the active site, augmented with further residues to preserve natural ribbon contiguity). Methyl groups were added to terminal residue backbone nitrogens to truncate the chain. The Rasmol software was used to carve the model residues from the PDB file, and hydrogens were added to the structures using the protonate facility of AMBER. For the small and intermediate models, constraints were placed on terminal carbon atoms for each chain to keep the model intact. No optimization constraints were used on the 7- and 10-angstrom models. Concurrent work is underway to study the energetics of model OP compound hydrolysis in water, as well as model OP compound-enzyme interactions including explicit waters, which will be reported elsewhere.

### **3. RESULTS AND DISCUSSION**

#### **3.1 Bare Enzyme**

NMR studies of the AChE active site structure suggest strong coupling between residues of the SER→HIS→GLU catalytic triad in the form of strong hydrogen bonding interactions. This H-bonded coupling is believed to be an essential factor in the proton transfer processes that enhance the catalytic nucleophilicity of such enzymes (Viragh et al., 2000). Specifically, the serine hydroxyl hydrogen is believed to experience a strong electrostatic attraction by a nitrogen on the nearby histidine ring. This interaction is stabilized by a short strong H-bond (SSHB) (alternatively known as a low barrier hydrogen bond or LBHB) between a nitrogenic proton on the histidine ring and the neighboring

unprotonated glutamic acid residue – an arrangement for which proton NMR studies have predicted an  $O_{\text{GLU}} - N_{\text{HIS}}$  SSHB distance of  $2.64 \pm 0.04 \text{ \AA}$  (Viragh et al., 2000).

A series of QM/MM calculations were performed on the 7- and 10-angstrom bare enzyme models of *Mus Musculus* AChE (Bourne et al., 1999) using both the ONIOM and SIMOMM codes without constraints. Various levels of theory for the QM portion and various force fields for the MM portion were investigated. Difficulties arose for all cases except the ONIOM 7 $\text{\AA}$  model with the Universal Force field (UFF) and the SIMOMM 10 $\text{\AA}$  model with the AMBER force field. In these two later models, the proper alignments of the catalytic triad residues were observed. The ONIOM 7 $\text{\AA}$  AChE (*Mus Musculus*) model using the B3LYP/3-21G\*\* level of theory for the QM portion and the UFF force field for the MM portion with the proper catalytic triad alignment is depicted in Figure 5.

In general, the effects of theory level and basis set size for the QM portion are quite minor for both the ONIOM 7 $\text{\AA}$  and SIMOMM 10 $\text{\AA}$  cases. The ONIOM 7 $\text{\AA}$  model consistently shows a minimum energy triad protonation state of  $\text{Ser}^0\text{-His}^-\text{-Glu}^0$ , where the  $\text{His-H}_\delta$  has effectively transferred to the Glu, while the  $\text{Ser-H}$  does not transfer to the His. The SIMOMM 10 $\text{\AA}$  model shows more sensitivity to basis set size in that calculations performed with the high layer at RHF STO-3G and RHF 3-21G show a minimum energy state of  $\text{Ser}^0\text{-His}^0\text{-Glu}^-$ . Calculations performed with the high layer at RHF 6-31G and 6-31G(d) converge to a protonation state of  $\text{Ser}^0\text{-His}^-\text{-Glu}^0$ . In this series of results, the AMBER force field has largely proven problematic. However, both methodologies do yield results with excellent alignment of the catalytic triad, and the ONIOM models have successfully reproduced the Short Strong Hydrogen Bond (SSHB) seen experimentally.

**Figure 5.** A 7 Å AChE (*Mus Musculus*) example. The QM (Ball and stick) portion contains the catalytic triad residues calculated at the B3LYP/3-21G\*\* level of theory. The MM (wire) portion, which surrounds the catalytic triad, is calculated using the UFF force field. Note the proper alignment of the catalytic triad. There are 254 heavy atoms plus 250 hydrogens in this example.

### 3.2 OP compound / Enzyme Calculations

Initial studies to locate transition states (TS's) included looking at the bare catalytic triad of AChE with Methyl Methylphosphonofluoridate, using only QM with G98. Two levels of theory, HF/6-31G(d) and B3LYP/6-31G(d,p), were investigated. The TS's for both levels of theory are depicted in Figure 6. The terminal methyl carbon atoms for serine, histidine and glutamate were locked in space while the other remaining atoms were allowed to fully optimize. In the HF/6-31G(d) level of theory, the main contributor to the imaginary frequency is the bond formation between the phosphorous atom and the O<sub>SER</sub> with minor contribution to the movement of the SER-200 proton moving to the N<sub>HIS</sub> (Figure 6A). This TS is dubbed a late TS due to the fact that the proton between the O<sub>GLU</sub>-N<sub>HIS</sub> has already formed a bond to the Glu-327 with a bond length of 0.98 Å. It is also important to point out

that there is no displacement of the proton between His-440→Glu-327 corresponding to the imaginary frequency in the HF level of theory. The transition state barrier for this reaction is quite high at 26.43 kcal/mol. In the B3LYP/6-31G(d) level of theory, the main contributor to the negative frequency is the displacement of the SER-200 proton moving to the His-440 nitrogen (Figure 6B). At the same time, there are two minor contributions to the imaginary frequency, which include the phosphorus- O<sub>SER</sub> bond formation and the movement of the proton between the SSHB O<sub>GLU</sub>-N<sub>HIS</sub>. The B3LYP level of theory is considered an earlier TS when compared to the HF level. The distance for the O<sub>GLU</sub>-N<sub>HIS</sub> SSHB in the HF and B3LYP levels are 2.76 and 2.58Å, respectively (Figure 6A and 6B). The B3LYP level of theory more accurately shows the simultaneous proton transfers in the catalytic triad and correlates to the empirical SSHB bond distances, as well as demonstrating a significant lowering of the TS barrier to 15.27 kcal/mol using the B3LYP/6-31G(d) level of theory.

**Figure 6.** The TS's of the AChE (*Torpedo Californica*) catalytic triad reacting with Methyl Methylphosphonofluoridate at the A) HF/6-31G(d) and B) B3LYP/6-31G(d,p) levels of theory.

With the TS's found in the bare minimum catalytic-triad calculations, the ONIOM QM/QM methodology was then used to map out energetics of the phosphorylation reaction. First, an ONIOM=(HF/6-31G(d):HF/STO-3G) calculation was performed where the terminal methyl group of Glu-327 was calculated using the STO-3G basis set and all other atoms were calculated using the 6-31G(d) basis set (not depicted). As above, all terminal carbon atoms

were frozen in space. The displacement of the TS imaginary frequency was identical to the QM HF level mentioned previously with the major contributor being the phosphorous- $O_{SER}$  bond formation. This produced a 26.40 kcal/mol reaction barrier that is comparable to the QM HF level above and to a rough 30 kcal/mol barrier found in related calculations of phosphonate hydrolysis in aqueous solution (to be reported elsewhere).

A second set of calculations was then performed in which the reactant, TS and product minima were located using the ONIOM=(B3LYP/6-31G(d,p):B3LYP/3-21G\*\*) levels of theory where the terminal ethyl group of Glu-327 formed the lower layer and all other atoms formed the higher layer (Figure 7). The displacement of the TS imaginary frequency was identical to the QM DFT calculation discussed in the previous paragraph with the major contributor being the displacement of the Ser-200 proton moving to the His-440 nitrogen. At the same time, there are two minor contributions to the imaginary frequency, which include the phosphorus- $O_{SER}$  bond formation and the movement of the proton between the  $O_{GLU}$ - $N_{HIS}$  SSHB. There is a 15.18 kcal/mol reaction barrier that is approximately half of the rough 30 kcal/mol barrier found in related calculations of phosphonate hydrolysis in

**Figure 7.** The reactant, TS, and product of the AChE (*Torpedo Californica*) catalytic triad reacting with Methyl Methylphosphonofluoridate using the QM/QM (B3LYP/6-31G(d,p):B3LYP/3-21G\*\*) levels of theory. The relative energies in kcal/mol and SSHB distances in angstroms are also depicted.

aqueous solution (to be reported elsewhere). The proper hydrogen bond scheme is obvious from the structures and an SSHB of 2.59Å is seen in both the reactant and product with a shorter SSHB of 2.52Å in the TS.

Additional residues beside the catalytic triad are postulated to play a role in the phosphorylation reaction. Figure 8 depicts the reactant and product of an ONIOM=(B3LYP/6-31G(d,p):B3LYP/STO-3G) QM/QM calculation of the *Torpedo Californica* active site structure, which includes the oxyanion hole (Gly-118, Gly-119 and Ala-201). It is important to stress that the OP compound is free to move without constraints. However, as depicted in Figure 8, the phosphonyl bond of the reactant (and product) coordinates in the oxyanion hole (3 hydrogens) with the fluorine atom *anti* to the O<sub>SER</sub>. The SSHB distance in the reactant and product is 2.65 and 2.63Å, respectively. While it is obvious from the reactant structure that the OP compound orients comfortably into the oxyanion hole before binding to the active site (and properly coordinates with the amide groups of the oxyanion hole backbone), the interaction is still stronger in the product structure. Distances between the substrate oxygen and Gly-118, Gly-119, and Ala-201 amide nitrogens in the product state are ~2.5Å with a roughly linear H-bond angle (~168-175°). Comparison of calculated charges between the product and reactant state show the substrate oxygen to have drawn negative charge in the product state relative to the reactant state, as expected. This important electrostatic stabilization bespeaks the necessity of treating the oxyanion hole residues quantum mechanically. The stereosensitivity of the OP compound-AChE interactions has been demonstrated experimentally (Ordentlich et al., 1999), and we have chosen here ostensibly the most reactive forms of the model OP compounds. Investigations of reactions involving different stereoisomers, presentation of different faces of the model OP compound to the serine residues (and thus affecting orientation into the

oxyanion hole and/or steric effects), and steric effects introduced by substitution of branched alkyl and alkoxy groups are currently under investigation and will be reported elsewhere.

**Figure 8.** Reactant and product for the phosphonylation of the active site with the presence of the oxyanion hole (Gly-118, Gly-119 and Ala-201). QM/QM calculation using the ONIOM=(B3LYP/6-31G(d,p):B3LYP/STO-3G) levels of theory.

All reactions discussed to this point have shown the product with the fluorine-leaving group still attached to the phosphorus atom. This trigonal-bipyramidal intermediate would then lose the fluoride atom via the participation of solvent molecules to produce a tetrahedral product. Previous calculations attempting to map out the energetics of this fluoride loss with the use of water and hydronium molecules on the same side of the fluorine (*anti* to the F-P- $O_{SER}$  angle) were unsuccessful. However, a unique TS through the participation of an ammonium ion has been located (Figure 9). This is a QM B3LYP/6-31G(d,p) calculation and as with previous calculation the terminal methyl groups are locked in space. This TS not

**Figure 9.** A QM B3LYP/6-31G(d,p) TS with the removal of fluorine via the participation of an ammonium ion.

only has the simultaneous dual catalytic triad proton transfer with the P-O<sub>SER</sub> bond formation, but also has the fluoride departure (P-F bond breakage) simultaneous with the F-NH<sub>4</sub> bond formation. This results in a TS with eight bonds being made/broken simultaneously correlating to one imaginary frequency. Another important aspect of this TS is the elimination of the trigonal-bipyramidal intermediate which correlates well with additional OP solvation calculations currently underway. Preliminary results mapping out the energetics of this reaction show the tetrahedral product is 68 kcal/mol below the TS, thus showing the importance of the fluoride departure. The activation energy is currently under investigation.

Other calculations have looked at the participation of a hydronium molecule and a hydronium molecule associated with a water molecule wrapped in a 14 and 16-membered ring configuration. These TS's (named Anaconda I and II, respectively), show the fluorine-coordinated solvent molecules wrapping around and coordinating with the O<sub>GLU</sub> of the catalytic triad creating electron flow through a 14 or 16-membered ring. These unique TS's show the importance of solvent molecule participation in the overall scheme (Anaconda II is depicted in Figure 10).

**Figure 10.** Anaconda II: A QM B3LYP/6-31G(d,p) TS with the removal of fluorine via the participation of hydronium and water molecules. Basically, a 16-membered ring with 12 simultaneous bonds being made/broken.

## CONCLUSIONS

This study represents the initial phase of a project devoted to application of a variety of theoretical methods to investigate reactions of model organophosphorus compounds in the active site of AChE. Mixed QM/MM methods have been used to estimate the sensitivity of the catalytic triad of the bare enzyme to details of the model and we have achieved insight into the reactions of model OP compound species with the AChE active site. Without high-level electronic structure methods, these calculations cannot accurately predict empirical results. The location of transition states, which is unarguably the most challenging aspect of computational endeavors, has produced novel solvent-participation mechanisms with as many as twelve simultaneous bonds being made/broken in a sixteen-membered ring correlating to one imaginary frequency.

Our results, which shed light on the underpinnings of the catalytic mechanism (to include the participation of solvent molecules), also produce data that is in agreement with empirical data. We expect future work to prove equally beneficial by exploring key structural features leading to reversible and irreversible binding to the enzyme, thereby obtaining definitive results on phenomena not readily accessible by traditional chemical or spectroscopic methods.

This document reports research undertaken at the U.S. Army Soldier and Biological Chemical Command, Soldier Systems Center, Natick, MA, and has been assigned No. NATICK/TR-03/024 in a series of reports approved for publication.
